Abstract

This report reviews the latest knowledge on boar semen diluents used in artificial insemination procedures. The requirements of an effective fresh semen diluent are discussed and currently available extenders are compared. Finally, we suggest directions to be taken in future research on this topic. A semen extender should be carefully selected according to its proposed use. For a planned semen storage time lower than 72 h, it is preferable to use a short-term extender. This type of diluent is less expensive and has been associated with a similar reproduction outcome to that of long-term extenders. When semen doses need to be stored for more than 4 days (because of long distances, disease control procedures, etc.), we recommend the use of a long-term extender on a higher sperm concentration to compensate for reduced sperm viability due to ageing. The semen extender must be selected on the grounds of optimal performance (in terms of fertility and litter size), which, in turn, depends on the particular conditions of each pig farm. The choice of extender is crucial given its profound effect on the economic viability of the artificial insemination programme.

Key words: artificial insemination, swine, diluent, spermatozoon, fertility.

Introduction

The artificial insemination (AI) of the pig was first performed by Ivanow in Russia at the start of the XXth century (Ivanow, 1907; 1922). In the 1930s, the procedure was developed at Russian state farms (Rodin and Lipatov, 1935; Milovanow, 1938) and over subsequent years, the practice of AI spread to other countries (USA, McKenzie, 1931; Japan, Ito et al., 1948). Following the studies performed by Chris Polge (1956), AI was reintroduced for swine production in the UK. The great advantage of AI is that the genetic potential of the best boars can be transferred to a large number of sows, leading to genetic improvements. However, the true development and wide commercial application of AI in pig production did not take place until the 1980s (reviewed in Reed, 1985; Crabo, 1990; Johnson et al., 2000) when insemination protocols were standardised. This almost entire century of deve-
Development has obviously also seen considerable advances in methods of collecting the semen from boars and preparing these semen doses, as well as continued progress in designing AI protocols for use in commercial settings.

Today, AI in pig production is widely applied throughout the developed world, although its extent of use in the different countries is highly variable. In Europe, this reproduction technique is generally extensively used, accounting for 80% of the reproductive gilts/sows in many countries (Holland, France, Germany, Spain, Norway, Finland, etc.). In contrast, the rate of AI use in the US is still low (around 50%), though these last few years have witnessed a notable increase. According to most recent estimates, some 19 million inseminations are performed world-wide per year, of which almost all (99%) are conducted using boar semen preserved at a temperature of 15-20°C (Johnson et al., 2000). Over 85% of these artificial inseminations are performed on the day or following day of sperm collection. The development of the AI technique in pig production has been mostly prompted by the dissemination of improved boar genes and the fact that results are equivalent or even better than those related to natural service.

This report analyses the economic and productive implications of the diluents used in porcine AI. Despite the established importance of the type of semen diluent used, this topic has not been extensively reviewed in the literature (Weitze, 1990; Reed, 1990; Althouse, 1997; Johnson, 2000; Levis, 2000). Our aim was thus to review —in the light of the most recently published findings— the significance of the choice of semen diluent in current conditions of pig production.

Diluents

By the term diluent, or extender, we mean the aqueous solution used to increase the volume of the ejaculate until that of the required dose. This needs to be done while preserving the functional characteristics of the sperm cells such that the appropriate sow fertility rate is maintained.

The spermatozoa are found in the seminal plasma, which supplies them with the necessary nutrients for the high metabolic demands of sperm transport through the female genital tract. In the ejaculate, this high metabolic activity can only be maintained over a limited period, as established in early studies on the preservation of boar semen (Lewis, 1911). Thus, to preserve spermatozoa for prolonged periods, their metabolic activity needs to be reduced by diluting it in an appropriate medium and lowering the temperature.

Given their particular features, boar spermatozoa are extremely sensitive to cold shock (Pursel et al., 1973a) which alters sperm viability. Specifically, this sensitivity seems to be related to the lipid content of the sperm cell membranes. Thus, when the temperature falls, lateral movements of membrane phospholipids are reduced and this causes separation of the lipid phases, which is associated with irreversible alterations to membrane proteins. The end result is that the function of the sperm membrane changes, compromising cell viability (reviewed in White, 1993). This reaction to cold shock means that in practice, semen samples need to be kept at 15-20°C, since a further reduced storage temperature limits their viability (Paulenz et al., 2000).

The need to preserve boar semen samples at these moderately reduced temperatures restricts their storage capacity since cell metabolism cannot be slowed down and because microbiological conditions may not be as effectively controlled as at lower temperatures (5°C).

In addition, dilution lowers the concentration of certain compounds in the seminal plasma, such as K+ (Harrison et al., 1978) or plasma proteins, altering sperm viability. These losses need to be compensated by adding ingredients to the diluent formulation such as bovine serum albumin (BSA), which has been shown to enhance motility (Waberski et al., 1989) and improve fertility rates derived from the use of preserved semen (Waberski et al., 1994a).

Types of diluent

At a practical level and for current production purposes, diluents can be divided into two major groups: those designed for short-term preservation (less than 1-3 days), and diluents for long-term semen preservation (over 4 days) (Table 1). The former are mainly used in short distance semen dose distribution networks (such as European systems in which semen doses are frequently produced at the farm itself), while long-term diluents are generally used in programmes such as those of the US or Norway, where the site of semen production is a long distance away from the site of insemination.
The advantages of long-term diluents include the possibility of: long distance transport, conducting diagnostic tests on semen before use, such as the polymerase chain reaction (PCR) to detect the presence of several viruses or a full analysis of semen quality, improving the organisation of tasks at semen collection centres and —to a large extent— this type of diluent helps distribute the semen samples to the reproduction farms.

The first Russian diluents were based on glucose solutions containing sodium or potassium tartrate or sodium sulphate and peptones, always ensuring electrolyte levels were low (reviewed in Foote, 2002a). Since then, in the 1950s, diluents for use in cow production based on egg yolk plus phosphate or citrate and milk were developed, and certain modifications for preserving boar semen were adopted (reviewed in Foote, 2002a). Of note among these was the adapted Illinois Variable Temperature diluent, which was used to preserve cattle semen at room temperature (du Mesnil du Buisson and Dauzier, 1959). The IVT medium is based on a solution of glucose, citrate, bicarbonate and egg yolk, but needs to be gassed with CO₂ to lower metabolic activity (Table 2).

The great innovation of the 1960s was the addition of a chelating agent (EDTA) to semen extenders, to block the action of calcium as a mediator of sperm capacitation and the acrosome reaction. It was at this time that the Kiev diluent appeared on the scene (Plisko, 1965) and subsequently became modified under several names (EDTA, Merck I, Plisko, Guelph). The Kiev diluent was responsible for the expansion of the AI of swine and is still successfully used today.

The exhaustive work performed at the Beltsville Center (USA) on possible methods of preserving boar sperm was the highlight of research on the topic in the 1970s. The team headed by Pursel and Johnson undertook numerous tests to develop diluents for cold storage (BL-1) (Pursel et al., 1973b) and freezing (BF-5) (Pursel and Johnson, 1975). Undoubtedly, their most far-reaching discovery was that of the BTS (Bets-

*: glucose monohydrate. BTS (Pursel and Johnson, 1975); Zorlesco (Gottardi et al., 1980); IVT (du Mesnil du Buisson and Dauzier, 1959); Kiev (Plisko, 1965); Modena (Moretti, 1981); Androhep (Weitze 1990); MR-A (Martin Rillo, 1984); ZORPV A (Cheng, 1985); Reading (Revell and Gossop, 1989).
ville Thawing Solution) medium (Pursel and Johnson, 1975), initially designed as a thawing medium and subsequently adapted for refrigerated semen (Johnson et al., 1988). BTS, probably the most widely used semen extender throughout the world, is characterised by containing a small amount of potassium. This feature preserves the sodium potassium pump and thus avoids intracellular potassium depletion which is related to reduced sperm motility (Alvarez and Storey, 1982).

The first of the so-called long-term diluents was the Zorlesco medium (Gottardi et al., 1980). This fairly complex medium is composed of Tris as a pH regulator, bovine serum albumin (BSA) and the amino acid cysteine. As other compounds with a sulphhydryl group, cysteine is a membrane stabiliser and capacitation inhibitor (Johnson et al., 2000). The use of this diluent in field conditions yielded poor results (Table 2), partly because of imbalances in its composition that lead to a low final osmotic pressure (240 mOsm). This was followed by the creation of the Modena diluent by Moretti (1981), who increased the proportion of glucose and removed the BSA of the Zorlesco medium only to find that fertility results were still unsatisfactory (Johnson et al., 1988; Laforest and Allard, 1996).

In a concurrent manner, Martín-Rillo and Alias developed the MR-A medium in Spain (Martín Rillo, 1984), and although its composition has not been disclosed to the public for commercial reasons, its performance as a long-term diluent up until now has been good.

In this same period, two long-term diluents were designed in the UK: ZORPVA (Cheng, 1985) and Reading (Revell and Gossop, 1989). Both are complex media based on a slightly modified Zorlesco medium in that they contain polyvinyl alcohol (PVA) as a macromolecule, improving the proportion of intact acrosomes. These diluents are more expensive (149-163%) than their short-term counterparts and their results do not surpass those obtained with other diluents (Reed and Curnock, 1990). It is due to these high costs, that their use has not become widely extended.

Weitze (1990) developed the Androhep diluent, comprised of Hepes as pH regulator and BSA to compensate for the dilution effect on seminal plasma proteins and for its slightly hypertonic nature (309 mOsm). This diluent has been well accepted in the swine production sector as a long-term semen extender.

Over the last few years, several new long-term diluents have emerged, as Acromax, X-Cell, Androhep Plus, Vital, SpermAid, Mulberry III, Safe Cell Plus, etc. Unfortunately, the quantitative composition of these media is unknown due to commercial interests, and though we do not doubt the quality of these diluents there is a lack of fertility data derived from comparative studies conducted at independent centres. Hence, we will need to wait for this information to become available.

Diluents used for freezing boar semen are based on egg yolk and glycerol as cryoprotecting agents, a high concentration of sugars and a detergent (Orvus et paste). The most commonly used diluents are the lactose-egg yolk medium (Westendorf et al., 1975) and the extender denominated BF-5 described by Pursel and Johnson (1975), whose composition includes glucose, egg yolk, and Tris as pH regulator. The BF-5 medium is used in freezing processes performed on semen pellets on dry ice.

**Diluent actions**

To perform its function, the extender should supply the nutrients needed for the metabolic maintenance of the sperm cell (glucose), afford protection against cold shock (BSA), control the pH (bicarbonate, Tris, Hepes) and osmotic pressure (NaCl, KCl) of the medium, and inhibit microbial growth (antibiotics).

**Nutrients**

The spermatozoon can produce the energy needed to maintain its cell metabolism and cause the flagellum to move, mainly through glycolytic pathways. These processes occur in the mitochondria located in the middle portion of the spermatozoon. The source of energy most commonly used in semen diluents is glucose, although other sugars have been tested (galactose, fructose, ribose or trehalose) but have generally yielded worse results.

**Regulating pH**

The pH of freshly ejaculated boar semen is around 7.4±0.2, similar to other body fluids. When this pH is reduced, both the sperm’s metabolism and motility are reduced. Its glycolytic metabolism (glucose is the main carbohydrate) leads to a reduced intracellular pH and consequently cell metabolism is suppressed. Lactic acid
is the main metabolite of this process and has been used as an indicator of semen quality (Rigau et al., 1996).

The addition of buffering agents therefore helps control the pH of the medium. The simplest buffers used are bicarbonate and sodium citrate, which show a limited buffering capacity. Other more complex buffers (TES, Hepes, MOPS, Tris) can control the pH over a wider range and are not temperature-dependent (MOPS and Hepes).

The pH of the diluents normally used ranges from 6.8 to 7.2 (Table 2), but it should be taken into account that in these media, the pH does not become stable until 60-90 min from the start of dilution in water and that the different extenders show a different pattern of pH change over time (Newth and Levis, 1999). Thus, appropriate measures need to be taken when preparing the diluent to avoid detrimental effects on preservation.

Osmotic pressure

The boar spermatozoon has an osmotic pressure of 290-300 mOsm, and can tolerate a fairly wide range of osmotic pressures (240-380 mOsm). Several authors have evaluated tolerance to different osmotic pressures, and concluded that neither motility nor viability are affected by osmotic pressures in the range 250 to 290 mOsm (Fraser et al., 2001). However, at pressures below 200 mOsm, motility is significantly reduced (Gilmore et al., 1996, Fraser et al., 2001).

Isotonic or slightly hypertonic diluents (300 mOsm) have provided best results in conditions of commercial use. Salts of inorganic ions such as sodium and potassium chloride are mainly used to regulate osmotic pressure.

Diluent costs

In general, costs related to reproduction represent a low proportion of the overall cost of pig production and have been estimated at 1.9% (Rouco and Muñoz, 1998). If we consider that most of this cost is associated with the human resources needed for diagnosing oestrus, semen collection and administering semen doses (Flowers and Esbenshade, 1993; See, 1996), the diluent represents an insignificant portion of complete production costs. Nonetheless, at artificial insemination centres that market semen doses, the choice of diluent does of course have its economic repercussions. Whichever the case, the cost of the extender is negligible compared to the possible consequences on farrowing rates and litter sizes.

The concept of diluent costs should not only include those needed to purchase its components but also those derived from its preparation. Thus, over the past few years, owing to high personnel costs, many laboratories opt for the use of powdered preparations (or concentrated liquid stock solutions) that only require diluting in distilled water. This method contrasts with in-house preparation, which involves separately weighing each component before final dilution.

The emergence of several firms that design and produce their own diluents has greatly extended the range of products offered and has given rise to a successful market and commercial activity (Pig International, 1998) in which there is intense competition among distributors. It may be said that, in general, long-term diluents are more expensive to produce than short-term ones, due to higher cost constituents such as Tris, BSA, etc., and the longer time needed to weigh the higher number of components (Reed, 1990).

Use of antibiotics

In most cases, the testicular tissue and accessory glands of the boar are bacteria-free, and therefore bacterial contamination of the ejaculate occurs during the semen collection process (Martin Rillo et al., 1998). An antibiotic needs to be added to the diluent since its components (glucose) and the temperature at which semen doses are stored (15-16ºC) promote the growth of most Gram negative bacteria (including Escherichia Coli and some Salmonella and Pseudomonas species).

Bacterial contamination mainly leads to a series of alterations including diminished sperm motility, sperm agglutination, or «clumping», an increased proportion of altered acrosomes and pH lowering to acidic levels (5.7-6.4) (Althouse et al., 2000). These factors all shorten the length of time semen doses can be preserved. Thus, adding an antibiotic at the appropriate concentration improves sperm survival and, in turn, improves fertility results (reviewed in Colenbrander et al., 1993). Further, the appropriate use of antibiotics could even represent a huge advance, if the conditions of hygiene in which semen is collected and the doses processed were also improved (Almond and Poolperm, 1996).

Penicillin plus streptomycin (1 g L⁻¹) was initially the combination most frequently used. Subsequent to this,
aminoglycosides were—and still are—successfully used including gentamicin, neomycin and kanamycin at concentrations around 200 mg L⁻¹. Most recently, new generation antibiotics (ceftiofur, apramycin, etc.) are being used, though no conclusive results are available yet.

At the legislation level, there are two reference organisations: the Office International des Epizooties (OIE) and the European Union (EU).

In its International Animal Health Code (2002), the OIE regulates the criteria to be applied to semen diluents. This norm basically recommends that if a diluent contains an ingredient such as milk, egg yolk or other animal protein, these should be pathogen-free or sterilised. The addition of antibiotics is permitted, provided they are declared in the corresponding international veterinary certificates.

In the EU setting, Directive 90/429/CEE (OJ, 1990), which regulates health policies applied to exchanges between member countries and the import of boar sperm, stipulates the use of a combination of antibiotics that should be efficient particularly against leptospirochaetes and mycoplasmas. Its concentration should at least have an effect equivalent to the following: 500 IU ml⁻¹ streptomycin, 500 IU ml⁻¹ penicillin, 150 mg ml⁻¹ lincomycin or 300 mg ml⁻¹ spectinomycin. This norm also indicates that immediately after adding the antibiotics, the diluted semen should be kept at a temperature of at least 15ºC for a minimum of 45 min.

### Fertility tests

The efficiency of semen extenders in reproduction terms has been extensively evaluated. First, we should consider that the relationship between semen quality (which the diluent preserves) and resultant fertility is not direct (Gadea et al., 1998; Gadea, 2001). Moreover, studies assessing boar semen diluents have been conducted in very different experimental conditions (animal species, environmental conditions, number of inseminations, number of spermatozoa per dose, time of AI, etc.). Thus, comparisons need to be undertaken with particular caution and the conclusions to be drawn are of a general nature and applicable only to the majority of cases.

### Preservation time

Several investigations have analysed the effect of storing boar semen in different diluents on fertility after AI. Thus, the diluent BTS (Hofmo, 1991) gives rise to a significant reduction in fertility when the diluted semen is stored for 48 h, while the total number of piglets born (TNB) and the number of piglets born alive (NBA) significantly decreases after 24 h of storage (Table 3). Similar results were obtained by Alexopoulos et al. (1996) who noted reduced fertility when the semen was stored for more than 72 h in BTS.

In contrast, Martinez et al. (1986) found that diluent MR-A was able to maintain the same fertility rate and number of live births using semen stored for up to 5 days (Table 4). In a subsequent study, however, it was concluded that fertility significantly decreases when semen is preserved in this medium for 7-8 days (84 vs. 67.3%) while litter size is not appreciably affected (11.1 vs 10.7) (Lyczynski and Kolat, 1996).

### Comparing diluents

Many studies have centred on evaluating the new diluents with respect to well known extenders. Of all the available data, we will discuss the most significant findings.

Although a higher sperm survival rate (measured as motility) has been observed with the long-term extenders (MR-A and Androhep) compared to the short-term extenders MR-A and Androhep.

TNB: total number of piglets born. Source: Martinez et al. (1986).
term diluent Kiev (Korniewicz et al., 1996), this difference was not significant when Androhep was compared to BTS (Waberski et al., 1994a). Recently, Huo et al. (2002) performed an interesting study on the quality of semen diluted in different media (Androhep, Zorlesco, BTS and Kiev) and stored for up to 15 days. Their findings indicated that sperm viability and mitochondrial activity exceeded 50% after 13 days of storage in long-term diluents (Androhep and Zorlesco).

The Kiev extender provided improved fertility results over those achieved with Beltsville liquid I (BL1) after 1 (74.5 vs. 64.7%) or 3 days (65.9 vs 60.5%) of storage (Johnson et al., 1982). In subsequent evaluations of short-term diluents, BTS was found to be more efficient than Kiev, Zorlesco and Modena in terms of fertility (Aalbers et al., 1983; Blichfeldt et al., 1988).

When we compared short-term diluents to those of long duration, no significant differences in fertility or litter size were generally noted in the first 3-4 days of storage, although the long-term extenders could be used for up to 7 days (Table 5). This is reflected by the results reported by Ratto and Jokinen (1990) when Kiev was compared to MR-A. Similar findings were described by Johnson et al. (1988), when they compared BTS to MR-A and Modena. These authors detected no significant differences between BTS and MR-A when used for up to 4 days of storage, but fertility rates and litter sizes were significantly improved over those recorded for Modena (Table 6) after AI of multiparous sows. However, these differences were diminished when the diluted semen was used to inseminate gilts, with no differences observed in litter size among the three diluents assessed. Similarly, Hofmo et al. (1998) noted no significant differences related to the use of BTS to preserve semen for 2-3 days compared to MR-A for 4-5 days.

Weitze (1990) compared the litter sizes obtained using semen stored for 3 or 5 days in Androhep, BW25 or Kiev (Table 7). No differences were recorded in terms of fertility. The study involved simple insemination using 2×10^9 spermatozoa per dose and the authors reported reduced litter sizes as the storage time increased. Later, when Waberski et al. (1994a) compared the media Kiev and Androhep used for storing semen for 2 to 5 days, they observed similar fertility results while the litter size was greater for Androhep after the fourth day of storage.

a,b: different letters in the same column indicate a significant difference at p<0.004. NBA: number of piglets born alive; TNB: total number of piglets born. Source: Johnson et al. (1988).
Finally, other studies have compared long-term diluents among themselves. Laforest and Allard (1996) in Canada compared the diluents MRA, BTS, Modena and Androhep and found no significant differences in fertility neither among the diluents nor according to the time of preservation (1-2 days vs 3-4 days). Only Modena was related to a discretely reduced total number of piglets born (TNB) after 3-4 days of storage. Kuster and Althouse (1999) analysed the use of Androhep and X-Cell, observing similar fertility results for the two diluents and the different number of days of semen storage (up until 5 days). However, Androhep was associated with reduced fertility on the sixth day of preservation and with a reduced litter size on the fifth day (Table 8).

**Future perspectives**

After almost a century of artificial insemination in swine, knowledge about the preservation of boar spermatozoa is still very limited and demands that future studies take the following directions:

a) Up until now, the design of new diluents has been based on an empirical model. In the future we will need to gain more insight into the sperm cell and its metabolism, and new models are needed to evaluate and optimise the diluent’s components (Pettit et al., 1999). Several additives are currently being evaluated that could affect sperm viability (e.g., alkyl-glycerol by Cheminade et al., 2002), protect against cold shock (Zeng and Terada, 2001) or improve sperm transport, synchrony with ovulation (Waberski et al., 1994b) and the fertilisation process (reviewed in Waberski, 1997; Kemp and Soede, 1997).

b) The possibility of preserving semen at temperatures below 15ºC would help reduce sperm metabolic activity and protect against the detrimental effects of microbial contamination. This type of investigation should address the cold shock problem. Several research teams are presently engaged in evaluating the effects of temperature on sperm survival (Althouse et al., 1998; Paulenz et al., 2000) and especially on fertility results. Althouse et al. (1998) reported similar results for fertility (93 vs 95%) and litter size (TNB, 11.58 vs 11.61; NBA, 10.68 vs 10.63) related to the use of semen stored for 60 h at 12 or 17ºC. Foote (2002b) has recently published promising results after preserving boar semen at 5ºC in media containing egg yolk.

c) Diluents also need to be adapted to individual differences among animals. Levis (2000) suggests the revision of several features of AI that have not been extensively explored including individual differences, since not all males interact in the same way with the diluents used (Weitze, 1990). Different breed-diluent interactions have also been described (Richter and Claus, 1990).

d) The use of new techniques such as deep intrauterine insemination, in which the number of spermatozoa per dose and insemination volume is reduced, could require new preservation conditions and accordingly, the diluent will need to be better assessed for this purpose (reviewed in Rath, 2002).

**Practical conclusions**

The choice of diluent should depend on its proposed use. When it is planned that the time from semen collection to use will be less than 3 days, the most rational choice would be to use a short-term diluent (of the BTS or Kiev type). The results of previous studies suggest no appreciable effects on semen quality or resultant fertility rates. Moreover, this type of diluent is less expensive and results are similar to those achieved with a long-term extender.

When the semen dose needs to be preserved for more than 4 days before insemination (in the case of long distances, health inspection of the semen, etc.) a long-term semen extender should be used and the sperm concentration of the dose should be increased. This precaution will compensate for any loss of sperm viability through ageing.

Whether a short- or long-term diluent is used, it should always be borne in mind that there are many factors than can affect the fertility results obtained. Thus, every effort possible should be made to optimise essential procedures such as oestrus diagnosis and selecting and processing the semen doses to ensure the best semen quality possible. The choice of diluent should always be aimed at optimising subsequent fertility rates and litter sizes in the particular conditions of each pig farm, since economic repercussions on production can be devastating.
